**ELECTRODE COATED WITH A FILM OBTAINED FROM AN
AQUEOUS SOLUTION COMPRISING A WATER-SOLUBLE
BINDER, PRODUCTION METHOD THEREOF AND USES OF
SAME**

FIELD OF THE INVENTION

The present invention relates to a new process for preparing electrochemical electrodes and electrodes thus obtained. The process makes it possible to prepare electrodes that are completely or partly coated with a film obtained by spreading and drying, on the electrode, an aqueous solution containing a water soluble binder and an active material.

A second aspect of the invention concerns processes for preparing electrochemical systems involving at least one step for preparing electrodes according to the invention and the electrochemical systems thus obtained.

A second aspect of the present invention relates to the use of a water soluble polymer, as a binder in an aqueous solution for the preparation of a film for coating part or the totality of an electrode.

The present invention also provides a new process for manufacturing a Li-ion natural graphite/electrolyte/LiFePO₄ battery, which is all liquid, all gel or solid.

PRIOR ART

United States Patent US-A-6,680,882 describes an aprotic electrolytic composition that is placed in a separator and in at least one composite electrode containing a powder of an active material. The electrolytic composition used comprises a first polymer matrix consisting of a polymer and at least one second polymer matrix as well as at least one alkali salt and a polar aprotic solvent. This process has the disadvantages associated with the use of binders of the PVDF type as diluted in solvents classified as toxic with respect to the environment.

BRIEF DESCRIPTION OF THE DRAWINGS

Figure 1 is a schematic representation of a process according to an embodiment of the invention for the preparation of lithium ion batteries by extrusion.

Figure 2 represents an elliptic cross-section of the elements of a lithium ion battery according to the invention.

Figure 3 is a schematic representation of a bi-cell structure for polymer cells.

Figure 4 is a schematic representation of a metal plastic wrapping without HF protection layer for non polymer batteries.

Figure 5 represents the charge-discharge curve of a graphite /Celgard (EC-DMC-LiBF₄)Li anode prepared with a water soluble binder.

Figure 6 represents the charge-discharge curve of a $\text{LiFePO}_4/\text{Celgard}$ (EC-PC-DMC- LiBF_4)Li cathode prepared with a water soluble binder.

SUMMARY OF THE INVENTION

The invention relates to a process for preparing an electrode that is at least partly coated with a film obtained by spreading and drying, on an electrode support, an aqueous solution comprising at least one active material, at least one water soluble binder and at least one water soluble thickener. Besides its economical advantages, the process overcomes the environmental problem involved when using organic solvents. The electrodes thus obtained are performing and can advantageously be used in the manufacture of electrochemical systems that are stable and highly performing.

DETAILED DESCRIPTION OF THE INVENTION

Within the framework of the present invention the term binder means any chemical compound whose function is to connect the active particles together in order to provide a chemical or electrochemical network that is favorable to conduction.

Within the framework of the present invention the term thickener means any chemical compound that is capable of increasing the viscosity and the wettability of the hydrophobic particles that are present in the concerned solutions.

A first object of the present invention consists of a process for preparing an electrode that is at least partly coated with a film obtained by spreading and drying, on an electrode support, an aqueous solution comprising at least one active material, i.e. chemically and/or electrochemically active, at least one water soluble binder and at least one water soluble thickener.

Spreading is advantageously carried out by traditional techniques described for example in Coating Technology Handbook by Satas Armek 1991, part II, Coating and Processing Technics pages 103 to 321. Drying of the film that is spread on the electrode is advantageously carried out for a period between 1 and 2 hours and at a temperature preferably between 80 and 130 °Celsius.

The active material used is advantageously selected from the group consisting of:

- metallic oxides;
- ceramics;
- carbon, natural graphite and synthetic graphite;
- metals;
- semi-conductor materials; and
- mixtures of at least two thereof.

According to another advantageous embodiment, the metallic oxide is selected from the group consisting of LiMn_2O_4 , LiCoO_2 and LiNiO_2 . For its part, the carbon may be selected from the group of high surface carbon, graphite, carbon fibers and cokes. The metals that are advantageously retained are selected from the group consisting of Ag, Sn and Cu. Among the semi-conductor materials, silicon gives particularly interesting results.

The chemically and/or electrochemically active material used is generally in the form of powder whose average particle size is between 10 nanometers and 10 millimeters and having a relatively low granular dispersion advantageously corresponding to a gap of $D_{50}-D_{10} = 30$ and a gap of $D_{90}-D_{50} = 30$.

According to a preferred mode, for example for the preparation of electrodes for automobile batteries, the powder that is retained has a granular dispersion between 200 nanometers and 25 micrometers.

At least 20 % of the binder and thickener retained are generally water soluble when they are introduced, at room temperature, at the rate of 20 grams in 200 grams of water. Preferably, at least 50 % and still more advantageously at least 90 % are soluble.

The water soluble thickener may be selected from the group consisting of natural celluloses, physically and/or chemically modified celluloses, natural polysaccharides, chemically and/or physically modified polysaccharides and which have a molecular weight between 27,000 and 250,000.

The thickener is advantageously selected from the group consisting of carboxymethylcelluloses, hydroxymethylcelluloses and methylethylhydroxycelluloses.

According to a preferred mode, the thickener is selected from the group consisting of carboxymethylcelluloses, of the Cellogen[®] type sold by Dai-

ichi Kogyo Seiyaku Co. of Japan for example under the commercial designations EP, 7A, WSC, BS-H and 3H.

The soluble binder is advantageously selected from the group consisting of natural and/or synthetic rubbers.

The binder is of the non fluorinated type or of the low fluorinated type. Indeed, by way of example, LiF, not being soluble in water, cannot be used in the context of the invention.

Among the rubbers, those of the synthetic type and more particularly those selected from the group consisting of SBR, (styrene butadiene rubber), NBR (butadiene-acrylonitrile rubber), HNBR (hydrogenated NBR), CHR (epichlorhydrin rubber) and ACM (acrylate rubber) are particularly advantageous.

The soluble rubbers used, and for example those of the SBR family, are preferably in the form of a paste.

By way of example, SBR sold by NIPPON ZEON'S BINDER BATTERY GRADE under commercial designation (BM-400B) or equivalent and the thickeners of the Cellogen[®] known under the abbreviations EP and/or 3H may be mentioned.

Normally, the thickener/binder ratio varies between 10 and 70 %, preferably between 30 and 50 %.

The binder content is advantageously between 1 and 70 %, and that of the thickener is between 1 and 10 %, in the aqueous solution.

An aqueous solution that is adequately used for spreading on an anode support may be formulated as follows, the percentages being given in weight:

- at least 64 % graphite; and
- at least 3 % water soluble binder,
- from 0.1 to 2% thickener; and
- at most 27 % water.

An aqueous solution adapted for spreading on a cathode support may be formulated as follows, the aqueous solution used for spreading containing by weight:

- at least 64 % LiFePO_4 ; and
- at least 3 % water soluble binder,
- from 0.1 to 2% thickener; and
- at most 27 % water.

When implementing the process, the electrode is dried by removing, preferably, at least 95 % of water that is present in the solution used to carry out the spreading step.

Various techniques known to one skilled in the art can be used to remove the traces of H_2O that are present at the surface of the electrode, after coating the latter with the aqueous solution. These traces of water are removed by thermal means on line of the EXT, DBH and/or DB process, or by infra red

at a temperature advantageously between 80 and 130 °Celsius for a period between 1 and 12 hours.

The film is advantageously dried until its residual water content is lower than 2000 ppm and preferably lower than 50 ppm.

This process is advantageously applied to electrodes of the non salted type, i.e. to the electrodes of the invention made of an active material, carbon and a thickener and/or a binder.

The process is usually carried out at room temperature and pressure. An inert atmosphere may be used, as well as a partial vacuum during the drying step. Because no organic solvents are used, the extrusion process is particularly important. Indeed, the risks inherent to the use of solvent, such as risks of explosion are set aside and the work can be carried out, for example according to an embodiment, by extrusion, under more energetic conditions, for example at extrusion speeds that can be as much as 20 % higher.

For the production of negative electrodes according to the invention, the electrochemically active material used may be selected from the group consisting of graphite, Sn alloys, Si alloys, $\text{Li}_4\text{Ti}_5\text{O}_{12}$, WO_2 type powders and mixtures obtained from at least two of these powders. By way of examples of such powders, those consisting of particles having an ellipsoidal graphite nucleus coated with prismatic shaped graphite particles, may be mentioned. Coating of ellipsoidal graphite with prismatic graphite may be obtained by mechano-melting and/or hybridization.

When it is desired to prepare a positive electrode, the electrochemically active material is preferably selected from LiCoO_2 , LiNiO_2 , $\text{Li}_2\text{Mn}_2\text{O}_4$, $\text{LiNi}_{0.5}\text{Mn}_{0.5}\text{O}_2$, LiFePO_4 powders that are coated with graphite and carbon and mixtures of at least two thereof.

For example, electrodes of the type LiFePO_4 coated with graphite and/or carbon can be obtained. Coating LiFePO_4 with graphite and/or carbon is normally carried out by mechano-melting and/or by hybridization.

The specific surface area of the carbon that is present in the coating may vary widely; the one measured by BET, was identified as being in most cases higher than or equal to $50 \text{ m}^2/\text{g}$.

This process also makes it possible to prepare an electrochemical separator that is at least partly coated with a film of the polymer type, preferably of the water soluble SBR type.

Such a process for preparing an electrochemical separator is in accordance with the processes of preparing electrodes as previously defined, except that the aqueous polymer solution used contains no active materials nor carbon or only very small quantities thereof. Indeed, the separator is used for ionic transport between the anode and the cathode, and it is not electronically conductive.

A second object of the present invention consists of an electrode that is made of a support that is coated at least in part with a film containing an active material, the electrode being obtained by implementation of one of the

processes according to the first object previously defined. These electrodes are characterized in that the binder, after drying the aqueous solution used to constitute the spreading film, is pulled away from the support.

In the case of a cathode, the electrode support advantageously comprises at least in part stainless, aluminum, copper, carbon, metal-plastic or a mixture of at least two of these materials.

In the case of an anode, the electrode support advantageously comprises at least in part copper, metal-plastic, or a mixture thereof.

The electrodes of the invention have advantageously at least one of the following properties:

- storage stability, preferably greater than 1 year, in the presence of a moisture content higher than 50 % and in the presence of temperatures higher than 20° Celsius;
- a film thickness, when the latter is graphite based, that is between 10 and 100 μm , still more preferably between 20 and 45 μm and according to the most advantageous mode the film has a thickness of about 45 μm ;
- a film thickness when the latter is iron and/or phosphate based, that is between 20 and 200 μm , still more preferably between 20 and 110 μm , the most advantageous mode being the one in which the film has a thickness of about 90 μm ;
- electrochemical performances that compare to those of corresponding electrodes obtained with the same active material but by using an organic solvent solution;

- an electrode film characterized by the fact that particles of rubber are directly attached to the electrode support; and
- a porosity of the film that coats one or more of the electrodes, measured by the method of measuring thicknesses, that is between 10 and 90 %, preferably between 30 and 40 %.

A third object consists of a process for preparing an electrochemical system by assembling its constituents including at least one anode, at least one cathode and at least one separator, in which at least one anode and/or at least one cathode has been obtained by a process according to the first object of the invention or as defined in the second object of the invention.

This process is advantageously used for the preparation of a battery in which the separator is porous. The separator is for example of the polypropylene or polyethylene type or of the (PP,PE) mixture type and obtained by extrusion, and/or of gel type.

The separator is preferably obtained from polymer materials of the type:

- polyester,
- poly(vinylidene fluoride), also called (PVDF), of chemical formula $(CH_2-CF_2)_n$, in which n preferably varies between 1000 and 4000, preferably such that n is close to 150; among those polymers those having an average molecular weight between 10,000 and 1 million, still more preferably those having an average molecular weight between 100,000 and 250,000 are particularly interesting;

- poly(vinylidene fluoro-co-hexafluoropropene) copolymers, of formula $[(\text{CH}_2\text{-CF}_2)_x(\text{CF}_2\text{-CF}(\text{CF}_3))_{1-x}]_n$ also called (PVDF-HFP), in which n varies between 1000 and 4000, preferably n varies from 2000 to 3000, still more preferably n is close to 150 and x preferably varies between 0.12 and 0.5; among those polymers, those having an average molecular weight between 10,000 and 1 million, still more preferably those having an average molecular weight between 100,000 and 250,000 are particularly interesting;
- poly(tetrafluoroethylenes), also called (PTFE), of chemical formula $(\text{CF}_2\text{-CF}_2)_n$, in which n varies between 5 and 20,000, preferably n varying from 50 to 10,000; among those polymers, those having an average molecular weight between 500 and 5 millions, still more preferably those having an average molecular weight between 5,000 and 1,000,000, preferably about 200,000 are particularly interesting;
- poly(ethylene-co-propylene-co-5-methylene-2-norbornenes) or ethylene propylene-diene copolymers, also called EPDM, preferably those having an average molecular weight between 10,000 and 250,000, preferably between 20,000 and 100,000; and
- poly(methylmethacrylates) also called (PMMA), of formula $[(\text{CH}_2\text{-C}(\text{CH}_3)(\text{CO}_2\text{CH}_3))]_n$, in which n preferably varies between 100 and 10,000, still more preferably n varying from 500 to 5000; among those polymers, those having an average molecular weight between 10,000 and 1 million,

preferably those having an average molecular weight between 50,000 and 500,000, are particularly interesting; and

- mixtures of at least two of these materials.

The preparation of this type of separator is advantageously carried out by utilizing the techniques described in Coating Technology Handbook by Satas Armek 1991, part II, pages 103 to 321, Coating and Processing Techniques.

By way of examples of known separators one may mentioned those of the PEO-PPO polyether copolymer type, those of the 3 branch polyether type as defined for example in US-A-6,190,804 or those of the 4 branch polymer type as defined in US-A-6,280,882. The content of these two patents and, in particular respectively columns 1 and 2, is incorporated by reference in the present application.

Particularly interesting results have been obtained by using a separator obtained from the 4 branch polyether manufactured by DKS Japan and sold under the trademark ELEXCEL[®] ERM1.

A fourth object of the present invention consists of electrochemical systems capable of being obtained by a process according to the third object of the present invention, as well as those comprising at least one electrode obtained by implementation of a process according to the first object of the present invention.

In systems of this nature one of the originalities resides in the fact that the polymer solution has dried at the surface of the electrode support and that the result, for example in the case of aqueous solutions of SBR, is a binding of SBR at the surface of the electrode support.

In systems of this nature, the separator may be of the gel, solid or liquid electrolyte type and it is advantageously of the gel type.

According to an advantageous embodiment, the electrolyte includes a least one salt and at least one solvent.

The molar concentration of salt in the electrolyte, is then preferably lower than or equal to 1, and the molar concentration of solvent, for its part, is advantageously higher than or equal to 1.

The salt that is used is preferably a salt of the imide family, of the type LiPF_6 , LiBF_4 , LiBOB , LiTFSI or LiFSI or mixtures thereof, such as a mixture of LiBOB and LiFSI .

The solvents used preferably have an high boiling point that is higher than 100 °Celsius. Such solvents may include those of the type γ BL, TESA, or modified TESA, or mixtures of at least two of these solvents.

EC (ethylene carbonate) and PC (propylene carbonate) solvents are normally used for the formation of a passivation film in the case of carbon based anodes, and the PC solvent is used to achieve low temperature applications.

In such systems, the electrolyte for the all gel battery is advantageously obtained from a precursor of a compound of a) a polymer + b) a liquid electrolyte.

The content of a) may vary between 1 and 99 %, preferably this content varies between 5 and 25 %; and the content of b) may vary between 1 and 99 %, preferably this content varies between 75 and 95 % and the contents a and b agree with the relation $(a) + (b) = 100 \%$, the % being given by weight.

According to another advantageous embodiment, the thermo-initiator is added in quantities that are in proportion to the total weight a) + b), i.e. preferably in amounts between 100 and 5000 ppm, still more preferably between 500 and 1000 ppm.

The composition of the polymer is preferably low i.e. about 5 % of a 4 branch polyether, preferably of the ELECEL[®] type and about 95 % of an electrolyte of composition (1.5 LiTFSI + EC + PC + TESA + γ BL (1 : 1 : 1 : 1)).

For its part, the lithium salt concentration is advantageously higher than or equal to 1 M (1 molar) in the case of gels, and the lithium salt concentration is lower than or equal to 1 M (1 molar) in the liquid electrolyte.

Among these electrochemical systems, one may advantageously mention those including at least one anode, at least one cathode and at least one separator and in which at least two, and preferably at least three of the

constituents of the system have been prepared by implementation of any one of the processes according to the first object of the invention.

Similarly, the electrochemical systems in which the constituents have been substantially prepared without using organic solvents, are particularly interesting, and those obtained without any organic solvent are preferred.

A fifth object of the present invention relates to the use of a water soluble polymer, preferably a polymer of the styrene butadiene rubber type, still more preferably a SBR sold by NIPPON ZEON'S BINDER BATTERY GRADE (BM-400B) as a binder in an aqueous solution for the preparation of a film for coating part or the totality of an electrode support.

This use has the advantage of being used, without any formation of HF, due to the fact for example of the use of an imide salt in place of LiPF_6 which is found in commercial batteries.

Preparation of the film is carried out by cross-linking the polymer solution that coats the electrode for example by thermal radiation after the electrode has been placed in the battery and the battery has been sealed.

The polymer solution is normally selected so that the polymerization temperature is between 40 and 80 °Celsius and so that cross-linking of the polymer solution is carried out by infra red.

The time of cross-linking of the polymer is advantageously between 5 minutes and 2 hours.

By way of example, polymerization is carried out at about 80 °Celsius and during about 10 minutes.

The use of the invention is particularly adapted for the manufacture of batteries of the flexible type such as those of the multi-layer metal plastic type.

This use allows a reduction of the manufacturing costs for example due to the fact that it is no more required to have a protective layer against HF and also due to the fact that the costs concerning organic solvents are eliminated.

Another particularly interesting application resides in the preparation of super condensers preferably in the preparation of super condensers of the hybrid type as well as in the preparation of cathodes from an aluminum type of support of the expanded metal EXMET® type.

Another interesting variant resides in the use of an anode support of the copper type, preferably EXMET, for the preparation of anodes, when the average voltage is lower than or equal to 1.6 Volts and the cathode support is made of aluminum when the average voltage is higher than 1.6 Volts.

DESCRIPTION OF PREFERRED EMBODIMENTS OF THE INVENTION

Generally, during implementation of the processes of the invention, the so called high speed techniques such as extrusion or vertical spreading on EXMET may be used, however extrusion is the recommended process.

The binder without fluorine is dissolved in water which facilitates the process of extrusion and increases the speed of the processes.

The presence of graphite in the anode and in the cathode acts as lubricant and makes it possible, for example, when utilizing extrusion, to homogenize the thickness of the electrode and to decrease its resistance by controlling porosity.

The solvent used, whether dealing with the anode or the cathode, is water, which makes the process safe, environmentally safe and not expensive. The use of an imide type of salt (without formation of HF) provides for a good conductivity of the electrolyte and increases the security of the battery.

The new process according to the invention is applicable for example to the production of inexpensive and safe Li-ion batteries. Such batteries include at least the 4 following parts: an anode; a cathode; a separator; an electrolyte.

EXAMPLES

The following examples are given purely as illustration and should not be interpreted as constituting any kind of limitation of the invention.

1. Use of the process for the preparation of an anode

The anode is made of spherical graphite particles having an average size of 20 μm , that are coated with 1 % of particles of a prismatic graphite whose size is 4 μm ; mixture is ensured by mechano-melting or by hybridization. In this manner, 95 % of graphite is mixed with 5 % of a SBR such as (NIPPON ZEON'S BINDER BATTERY GRADE (BM-400B)) that is used as binder, the latter being put into solution in water.

An optimum concentration is selected for the extrusion or spreading on copper (preferably on an expanded metal called EXMET).

The spherical graphite is selected because of the lithium diffusion speed at its surface and of its reversible capacity of the order of 370 mAh/g. For its part, prismatic carbon is selected as a conductivity bridge between the spherical particles, which decreases the resistance of the electrode. The purpose of using prismatic graphite (associated with the presence of basal surfaces) is to make sure that the electrode is lubricated; in particular during extrusion or spreading, which has the effect of homogenizing the thickness and the porosity of the electrode. On line drying by infra red simplifies the machinery and the process.

Heating is also used to remove traces of water (H_2O). The fact that the electrode is not salted (no salt) permits to improve the electrochemical performances of the battery without production of HF.

The other advantage associated with this electrode is the use of a non fluorinated binder, which eliminates all reaction with the electrolyte or all

parasite reaction with formation of HF. This has an influence on the choice of the multilayer material, of the metal plastic that is used as battery casing and makes it possible to prevent using a protective layer against HF, which limits by as much manufacturing costs.

In this process, the starting solvent is water. This is beneficial to the environment and requires no special installation (such as an anhydrous chamber for the recovery of the solvent with special precautionary measures).

2. Use of the process for the preparation of the cathode

The cathode preferably consists of LiFePO_4 (from Phostech Inc.). LiFePO_4 is coated with 3 % Ketjen black and 3 % natural or artificial graphite. The coating process is made possible by mechano-melting or by hybridization.

Ketjen black is used to constitute the electronic conductivity network in the electrode. Graphite has a double function. First, it provides a junction bridge between LiFePO_4 and Ketjen black, which brings a low resistance to the electrode. Graphite also acts as lubricant to facilitate spreading, in particular by extrusion, by providing an electrode with a good uniformity and a controlled porosity.

The compound LiFePO_4 /carbon (Ketjen black)/graphite is mixed with 5 % SBR binder, from (NIPPON ZEON'S BINDER BATTERY GRADE (BM-400b)) that is put in solution by dissolution in water.

Spreading of the composite is carried out by extrusion or by Doctor Blade (horizontal or vertical), preferably by extrusion. Drying is achieved as in the case for the preparation of the anode described in part 1, that uses infra red.

The process that is used for the preparation of the cathode is similar to the one used for preparing the anode.

It requires the use:

- of H₂O as solvent;
- of a lubricating and conductive graphite;
- of infra red as drying means; and
- of a binder without fluorine of the type SBR; (NIPPON ZEON'S BINDER BATTERY GRADE (BM-400B)).

It permits to prevent using:

- a salt;
- an anhydrous chamber; and
- special precautionary measures.

LiFeO₄ is completely charged at 3.8 Volts, without for this reason decomposing the SBR of (NIPPON ZEON'S BINDER GRADE(BM-400B)).

The use of an imide type of salt has no effect on the corrosion of the aluminum collectors, preferably of the type EXMET, which is advantageous for the energy density of the battery.

3. Process for preparing a separator

a. Separator for liquid and electrolyte gel

The separator is preferably of the PP (polypropylene) or PE (polyethylene) type or mixtures thereof. It is preferably obtained by extrusion. The porosity of this separator is about 30 to 50 %, which gives more space for the electrolyte and in particular for the gel. This membrane is called "Free Solvent". The separator is cross-linked by UV thermal heating, E-Beam, or IR (thermal). Cross-linking is preferably carried out by IR on a protection line.

b. Polymer separator

The use of this separator in the battery still limits the use of PP or PE. The advantage of a separator made of a polymer is for security reason, since it forms a physical and chemical gel with the electrolyte.

The separator is preferably made of a polyether of the PEO-PPO copolymer type (polyoxyethylene – polyoxypropylene) of the 3 branch or 4 branch type, preferably a 4 branch polyether (sold by DKS under the designation Elexel[®] 217). These polyethers are practically liquid at room temperature. Their use within the framework of the extrusion process requires no addition of solvent, which overcomes the problem of harms to the environment.

Cross-linking of this type of polymer is carried out thermally by E-Beam, IR or UV.

4. Assembling a Li-ion battery (Figs. 1-4)

a. All liquid

The three films anode/separator: PP or PE/cathode are wound together according to the desired capacity (in mAh or Ah); when winding, a pressure of 10 psi is applied. Tabs (current connectors) of the Al and nickel type are welded by ultrasound (ATM207), respectively on the Al collector of the cathode and the copper of the anode.

The 3 film winding is introduced into a metal plastic bag, without HF protector.

Injection of the liquid electrolyte is carried out after achieving a complete vacuum in the metal plastic bag. The liquid electrolyte is a mixture of salts and solvents, the salt is of the imide type such as LiTFSI and/or LiFSI, the solvent or the mixture of solvents used preferably has a high boiling point. By way of example of solvents that can be used in this context, the following mixtures are mentioned:

EC + γ BL

EC + TESA (or modified TESA)

or

PC + EC + γ BL

PC + EC + TESA (or modified TESA)

PC + EC + γ BL + TESA (or modified TESA)

Concentration of the salt in the case of liquids is ≤ 1 M (1 molar). Once the battery has been sealed, the electrochemical formation of the battery is carried out by applying small currents to obtain a uniform passivation film on the surface of the anode (graphite/ellipsoid).

b. Gel with PP or PE separator

The process of part 4b is essentially the same as the one described in part 4a.

The electrolyte gel precursor is made of 5 % polymer (Excel) + 95 % (1.5 M LiTFSI) + EC + PC + γ BL 1 : 1 : 3) + 1000 ppm of a thermo-initiator that is preferably Perkadox 16. This combination does not limit the choice of the electrolyte.

The electrolyte is injected after achieving a complete vacuum in the bag of the battery, including the 3 films (anode/separator PP/cathode).

Once the battery has been sealed, the gel is obtained by thermal treatment at 80 °Celsius, during 10 minutes, preferably by IR during 10 minutes. An in situ impedance measurement follows the evolution of the resistance of the electrolyte. After implementation of the polymerization, the battery is electrochemically formed, as in the equivalent portion of part 4b. The gel concentration is then constant in the separator, in the anode and in the cathode.

c. Gel with polyether separator

The 3 films anode/polyether/cathode are wound together and are introduced into a bag of the metal plastic type. The gel precursor is of the same nature as the precursor already described in part 4b). The gel precursor is introduced in the metal plastic bag after a complete vacuum. Polymerization is obtained at 80 °Celsius during 10 minutes or preferably

with IR (infra red) once the battery has been sealed. A formation as in the case of 4b is applied to the battery. The gel concentrations in the separator and in the electrodes are different.

5. Other technologies

The implementation of this new process is not limited to the use of graphite as active material of the anode or to the use of LiFePO_4 as active material of the cathode.

By way of example, a few anodes of the type Si, $\text{Li}_4\text{Ti}_5\text{O}_{12}$ or Sn based alloys or the like may be mentioned; the cathode may comprise LiCoO_2 or $\text{LiMn}_{0.5}\text{Ni}_{0.5}\text{O}_2$, $\text{LiNi}_x\text{Co}_y\text{Al}_z$ or the like.

The gel may also be of the PVDF type or may consist of a mixture of polyether + PVPF or polyether + PMMA or the like.

The process may easily be adapted for a hybrid super condenser of the type:

- 5a) $\text{Li}_4\text{Ti}_5\text{O}_{12}$ /electrolyte/carbon;
- 5b) WO_2 /electrolyte/carbon;
- 5c) Graphite/electrolyte/carbon; and
- 5d) Si/electrolyte/carbon or other combination.

Example 1:

Production of the anode is carried out by using a spherical graphite whose particles have an average size of 20 μm . These particles have been obtained by mechano-melting (Hosokawa, Japan). 95 % of graphite is

mixed with 8 % of STYRENE BUTADIENE RUBBER (STYRENE BUTADIENE RUBBER (SBR)) dissolved in water. This mixture is applied on a copper collector by the Doctor Blade[®] method. The electrode thus obtained is dried under vacuum at 120 °Celsius during 24 hours. This electrode is mounted opposite a metallic lithium and it is separated by a Celgard (EC-DMC-LiBF₄) type of film. There is thus obtained an electrochemical cell with a 4cm² surface.

The battery is cycled between 0.0 and 2.5 Volts at a rate of C/12. Figure 5 shows the result of the first two cycles of the cell with a coulombic efficiency of 82.0 % and 96.1 % respectively during the first and second cycles.

Example 2:

The cathode that is prepared contains particles of LiFePO₄ (Phostech Inc.) coated with 3 % Ketjen black. The coating process is carried out by mechano-melting (Hosokawa, Japan).

The compound LiFePO₄/carbon (Ketjen black) is mixed with 5 % of STYRENE BUTADIENE RUBBER (STYRENE BUTADIENE RUBBER (SBR)) dissolved in water. This mixture is applied on an aluminum collector by the Doctor Blade[®] method. The electrode thus obtained is dried under vacuum at 120 °Celsius during 24 hours. This electrode is mounted opposite a metallic lithium and is separated by a Celgard type of film (EC-PC-DMC-LiBF₄). There is thus obtained an electrochemical cell with a 4cm² surface.

The battery is cycled between 2.5 and 4.0 Volts at a rate of C/24. Figure 6 shows the electrochemical result of the first two cycles of the cell with a coulombic efficiency of 90.0 % and 99.7 % respectively during the first and second cycle.

Although the present invention has been described by means of specific embodiments, it is understood that many variations and modifications may be grafted to said embodiments, and the present invention aims at covering such modifications, uses or adaptations of the present invention following in general, the principles of the invention and including any variation of the present invention that will become known or are conventional in the field of activity of the present invention, and that may apply to the essential elements mentioned above, in accordance with the scope of the following claims.
